1 Introducing F*

F* (Swamy et al., 2016) is a verification system for ML programs that allows a novel combination of manual and automatic proofs. This enables the scalable verification of functional correctness and security for more realistic applications, such as a reference implementation of the TLS protocol framework. F* puts together full dependent types, monadic effects, refinement types, and a weakest-precondition calculus. Verification conditions in the dependently-typed higher-order logic of F* are encoded to SMT formulas and discharged automatically using Z3. In addition, F* provides some of the power and expressiveness of a proof assistant like Coq, which enable users to prove arbitrarily complex properties manually. In this talk we will explain the main ideas behind F*’s SMT encoding (§2) and present ongoing work on formalizing it for a core subset of F* (§3). We conclude with related work (§4).

2 From F* to SMT

Verification conditions in the dependently-typed higher-order logic of F* are encoded to SMT formulas and discharged automatically using Z3. This nontrivial encoding tries to strike a pragmatic balance between completeness and practical tractability. For this the encoding combines (1) a deep and a shallow embedding of F* terms, (2) allows bounded unrolling of recursive and inductive definitions, and (3) performs lambda lifting for eliminating higher-order functions.

The following F* function computing a factorial illustrates some of this:

type nat = x:int{x>=0}
val factorial: nat -> Tot nat
let rec factorial n = if n = 0 then 1 else n * (factorial (n - 1))

The refinement type x:int{x>=0} denotes the integers that are greater than or equal to 0, that is, the naturals. For the nat type definition, the SMT encoding generates the following very intuitive formula:

(assert (forall ((@x Term))
  (! (iff (HasType @x nat)
    (and (HasType @x int)
      (>= (BoxInt_proj @x) 0))))
  :pattern ((HasType @x nat))))

Submitted to:
HaTT 2016
The pattern \texttt{HasType @x nat} is bound to the quantifier by the reserved symbol bang (!), and allows the SMT solver to instantiate the \texttt{forall} whenever it encounters an SMT term that matches the left hand side of the equivalence. In the case above, whenever there is an SMT term of the form \texttt{(HasType y nat)} for some SMT term \texttt{y}, the solver will try to instantiate the quantifier as a formula of the form

\[
\texttt{(iff (HasType @x nat)} \\
\texttt{(and (HasType @x int)} \\
\texttt{(>= (BoxInt_proj @x) 0)))}
\]

Sort \texttt{Term} denotes an open data type (open to capture the ability to always add new inductive types in F\textsuperscript{*}) and \texttt{BoxInt} is a constructor taking an \texttt{Int} and returning a \texttt{Term}. In the formula above, \texttt{BoxInt_proj} projects the integer out of a term that has type \texttt{int}. F\textsuperscript{*} arithmetic operations are encoded in terms of the SMT solver’s ones; for instance multiplication on \texttt{Term}s is defined as follows:

\[
\begin{align*}
\texttt{(declare-fun op_Multiply (Term Term) Term)} \\
\texttt{(assert (forall ((@x0 Term) (@x1 Term))} \\
\texttt{(! (= (op_Multiply @x0 @x1) \\
\texttt{(BoxInt (* (BoxInt_proj @x0) (BoxInt_proj @x1))))))} \\
\texttt{:pattern ((op_Multiply @x0 @x1)))))
\end{align*}
\]

Since we marked the \texttt{factorial} function as total (Tot), F\textsuperscript{*} needs to show its termination by proving that the recursive call \texttt{factorial (n - 1)} is done on a “strictly smaller” argument. For this, F\textsuperscript{*} asks the SMT solver to prove that \texttt{n - 1} is strictly smaller than \texttt{n}, using the following idealized SMT query:

\[
\begin{align*}
\texttt{(declare-fun n () Term)} \\
\texttt{(assert (not (implies (and (HasType n nat) (not (= n (BoxInt 0))))} \\
\texttt{(Valid (Precedes (op_Subtraction n (BoxInt 1)) n))))))
\end{align*}
\]

If the SMT solver proves this negative formula unsatisfiable then F\textsuperscript{*} concludes that \texttt{factorial} terminates. For this, F\textsuperscript{*} defines a well-founded ordering on all values \texttt{Precedes}, which for naturals is the usual less than relation. The \texttt{Precedes} relation is deeply embedded and given meaning in the SMT solver by a \texttt{Valid} predicate. For instance, the ordering on naturals can be axiomatized as follows:

\[
\begin{align*}
\texttt{(assert} \\
\texttt{(forall ((@x1 Term) (@x2 Term))} \\
\texttt{(! (implies} \\
\texttt{(and (HasType @x1 int) (HasType @x2 int)} \\
\texttt{(>= (BoxInt_proj @x1) 0) (>= (BoxInt_proj @x2) 0)} \\
\texttt{(< (BoxInt_proj @x2) (BoxInt_proj @x1))))} \\
\texttt{(Valid (Precedes @x2 @x1))))} \\
\texttt{:pattern ((HasType @x1 int) (HasType @x2 int)} \\
\texttt{(Valid (Precedes @x2 @x1))))))
\end{align*}
\]

While in this simple example, \texttt{Valid of Precedes} could be represented as just a FOL predicate, F\textsuperscript{*} allows type- and formula-level computations, which can also be performed by the SMT solver. For instance, in a more complex example the \texttt{Precedes @x2 @x1} formula above could be computed by applying a type-level function to arguments.

 Afterwards, F\textsuperscript{*} needs to prove that \texttt{factorial} returns a \texttt{nat}. To encode this, first it defines an arbitrary natural \texttt{n} that stands for the argument to \texttt{factorial}. Afterwards, F\textsuperscript{*} admits that for every term \texttt{x} preceding \texttt{n}, \texttt{factorial x} has type \texttt{nat}.

\[
\begin{align*}
\texttt{(declare-fun n () Term)} \\
\texttt{(assert (HasType n nat))}
\end{align*}
\]
Aguirre et al.

(\text{assert (forall ((@x Term))}
  (! (implies (and (HasType @x nat) (Valid (Precedes @x n)))
   \begin{itemize}
   \item (HasType (factorial @x) nat)
   \end{itemize}
  ):pattern ((factorial @x))))

Finally, we use the assumption above to check that \text{factorial} returns a \text{nat}. In the base case this check is trivially $1 \geq 0$. For the recursive case, \text{F}^* has to prove that $n \cdot \text{factorial}(n-1) \geq 0$, knowing that $n$ is a \text{nat} different from 0. This condition is encoded as the following SMT query:

(\text{assert (not}
  (\text{ite (BoxBool_proj (op_Equality int n (BoxInt 0)))}
   (\geq 1 0)
   (\geq (BoxInt_proj
   \text{(op_Multiply n}
   \text{(op_Subtraction n (BoxInt 1)))) 0 ))))

Once \text{factorial} has been verified to be total its definition can be used in specifications (e.g., refinements), so we want to allow the SMT solver to perform computations that unroll \text{factorial}. For this we encode the body of the \text{factorial} function as an equivalent SMT function. For efficiency, we only allow the SMT solver to perform bounded unrolling of recursive functions. For this, we define a new SMT function (\text{factorial}_\text{fuel}) that takes an additional fuel argument, which controls the number of times it can be unrolled. The fuel sort is defined as an unary natural number with \text{ZFuel} and \text{SFuel} as the constructors:

(\text{declare-datatypes () ((Fuel (ZFuel) (SFuel (prec Fuel))))})

(\text{declare-fun MaxFuel () Fuel}
(\text{assert (= MaxFuel (SFuel (SFuel ZFuel))))})

\text{MaxFuel} is a parameter that can be overridden by the user. For instance, the definition above sets \text{MaxFuel} to 2, which is the current default in \text{F}^*.

The following equation defines the fuel-instrumented function using a recurrence relation. Notice that the recursive call is made with one less fuel unit, ensuring that the unrolling can only happen a bounded number of times (determined by \text{MaxFuel}). When the fuel runs out \text{factorial}_\text{fuel} is not interpreted.

(\text{assert}
  (\text{forall ((@f Fuel) (x Term))}
   (! (implies (HasType x nat)
     (= (factorial\_fuel \text{(SFuel @f)} x)
       (\text{ite (= (op_Equality int x (BoxInt 0))) (BoxBool true))
         (BoxInt 1)
         (op_Multiply x
           (factorial\_fuel \text{\@f}
             (op_Subtraction x (BoxInt 1)))))))
   ):pattern ((factorial\_fuel \text{(SFuel \text{\@f}) x}))))

Another equation relates the original and the fuel-instrumented \text{factorial} SMT functions:
From $F^*$ to SMT

\[ t ::= \text{nat} \mid x : t_1 \rightarrow t_2 \mid x : \{ \phi \} \]
\[ \phi ::= e_1 < e_2 \mid e_1 = e_2 \mid \phi_1 \Rightarrow \phi_2 \mid \phi_1 \land \phi_2 \mid \forall x : t. \phi \]
\[ n ::= \text{O} \mid S n \]
\[ v ::= n \mid \lambda x : t. e \mid \text{let rec } (f : d : t) x = e \]
\[ e, d ::= x \mid v \mid e_1 e_2 \mid S e \mid \text{pred } e e_0 e_S \]

Figure 1: Syntax of the fragment

The $F^*$ encoding also uses lambda lifting for eliminating first-class functions. An SMT function called $\text{ApplyTT}$ is defined for representing function applications. In the case of factorial, we introduce a fresh token $\text{factorial@tok}$ for which we define $\text{ApplyTT}$ as follows:

\[
\begin{align*}
\text{assert} \ (\forall x : \text{Term}) \\
\quad (\forall (\text{factorial@tok}) (\text{factorial@tok}) : \text{pattern} ((\text{factorial@tok})))
\end{align*}
\]

3 Ongoing formalization

We are currently formalizing in Coq the SMT encoding for $pF^*$ (read "pico $F^*")", a fragment of $F^*$ that includes dependent function types, refinement types, fixpoints with semantic termination check, a well-founded ordering on naturals and subtyping. Its syntax can be seen on Figure 1.

An expression $e$ in this language can be a variable $x$, a value $v$, an expression $e_1$ applied to another $e_2$ (written $e_1 e_2$), a successor of an expression $e$ (written $S e$), or the destructor $\text{pred } e e_0 e_S$, that reduces to $e_0$ or $e_S n$ depending on whether the first argument reduces to $O$ or to $S n$. A value $v$ is either a natural number, which is constructed from $O$ and successor $S$, a lambda abstraction or a recursive definition $\text{let rec } (f : d) x = e$, where $d$ is a ranking function ensuring its termination. A type $t$ is $\text{nat}$, a dependent function type $x : t_1 \rightarrow t_2$, or a type $t$ refined by a logical formula $\phi$ (written $x : t \{ \phi \}$).

In this fragment we have typing judgments of the form: (1) $\Gamma \vdash e : t$, where $\Gamma$ is a typing environment relating variables to types, $e$ is an expression, and $t$ is a type; (2) formula well-formedness $\Gamma \vdash \phi$; and (3) a logical validity judgment of the form $\Gamma \models \phi$.

For the formalization we have embedded into Coq the syntax of $pF^*$ and FOL with arithmetic, as well as the Tarski semantics $\llbracket . \rrbracket$ of FOL with arithmetic that maps SMT formulas to $\text{Prop}$. The logical encoding $\llbracket . \rrbracket$ maps $pF^*$ formulas to SMT formulas and $pF^*$ expressions to SMT terms.

The main property we are in the process of proving is the following:

If $\Gamma \vdash \phi$ and $\llbracket [\Gamma] \rrbracket \rightarrow \llbracket [\phi]_r \rrbracket$ then $\Gamma \models \phi$.

A particularly interesting case for $\phi$ is the one of equality $(e_1 = e_2)$, for which we need to prove:

If $\Gamma \vdash e_1 : t$ and $\Gamma \vdash e_2 : t$ and $\llbracket [\Gamma] \rrbracket \rightarrow \llbracket [e_1]_r = [e_2]_r \rrbracket$ then $\Gamma \models e_1 = e_2$. 

4 Related work

Translations from HOL to FOL have been implemented in the past (Meng and Paulson 2008; Benzmüller et al., 2015; Brown 2013; Blanchette et al., 2016b) and even sometimes partially formalized (Blanchette 2012; Blanchette and Popescu 2013; Blanchette et al., 2013b, 2016a; Czajka 2016). In particular, Sledgehammer (Paulson and Blanchette 2010; Blanchette et al., 2013a) allows proving Isabelle/HOL proof goals by translation to FOL provers and SMT solvers. Similar tools have been build for HOL Light and HOL4 (Kaliszyk and Urban 2014) as well as for Mizar (Kaliszyk and Urban 2015). However, our use case is different in F*, since we target efficient, scalable, and reproducible SMT solver behavior and the soundness of the encoding, while hammers often do not aim for reproducibility and attempt to reconstruct a proof term after the fact to recover soundness. Extending hammers to dependent types is a topic of ongoing research (Czajka and Kaliszyk 2016; Czajka, 2016).

Counterexample finders such as Nitpick (Blanchette and Nipkow 2010) and Nunchaku (Cruanes et al., 2016) rely on different kinds of translations from HOL to FOL. Extending counterexample finders to dependent types is also a topic of ongoing research (Cruanes and Blanchette 2016).

F*’s bounded unrolling of recursive and inductive definitions was influenced by previous work in Dafny on “computing with an SMT solver” (Amin et al., 2014). Such fuel bounds are also used in counterexample finders like Nitpick (Blanchette and Nipkow, 2010) and Nunchaku (Cruanes et al., 2016).

Why3 (Filliâtre and Paskevich, 2013) encodes higher-order functions using lambda lifting (Clochard et al., 2014) and provides a Coq tactic called why3 that can revert the translation from Why3 to Coq.

Lean (de Moura and Selsam, 2016; de Moura et al., 2015; Lewis and de Moura, 2016) is an ongoing effort to implement better automation for type theory. Encoding F* into Lean is the subject of ongoing experiments.
